# Chapter-5

**Discussion and Conclusions**

## 5 DISCUSSION AND CONCLUSIONS.

### 5.1 Outcomes and conclusions.

The two major outcomes of the study are the “corrosion map”, which is a representation of corrosion levels of steel, copper and aluminum in the atmospheric environment of Sri Lanka and the calculation of energy conservation through preventing steel corrosion by galvanizing.

The “corrosion map” provides the corrosion rate in  $\mu\text{m}/\text{annum}$  for zinc or galvanized steel exposed to the atmosphere. If the district and divisional secretariat is known then a value for zinc corrosion and the corrosion category as per ISO 9224 can be known. The corrosion category and the zinc corrosion rate in  $\mu\text{m}/\text{a}$ , are presented in appendix A with a map of each district. Once the atmospheric category is known it is a simple matter to find out the corrosion rates of copper and aluminum just by referring Table 12: Guiding corrosion values for corrosion rates ( $r_{av}, r_{lin}$ ) of carbon steel, weathering steel, zinc, copper and aluminum in atmospheres of various Corrosivity categories.[19 ].

Once corrosion rates are known from the map, predictions can be made on the lifetime of the galvanized coating. Suitable metals can be selected using the corrosion rates in  $\mu\text{m}/\text{a}$ . Appropriate corrosion prevention can be specified.

The “Corrosion Map” will be very useful for major uses of steel in the country when specifying steel structures. Electrical and telecommunication utilities having a network of steel structures to distribute power or telecommunication signals, can use the map to predict the lifetime, and prepare maintenance plans for the steel structures in its network.

The wind map of Sri Lanka was completed recently and a huge potential of wind energy was predicted at various sites round the country. The harnessing of wind energy involves a lot of steel work. The corrosion map can be effectively used to calculate the life time of structures and specification of corrosion prevention methods in the areas identified as good wind sites.

The commercial capital Colombo is the most corrosive part in the island mainly due to its location close to the sea, the high rainfall and population density. Most of the buildings in the Colombo metropolitan area face severe corrosion problems reflecting the results predicted by the study. If Colombo had been a 2 km further to the coast, the cost of corrosion in Colombo would have come down by a huge amount. By analyzing the corrosion map it could be seen that areas within 1km from the coast has the highest corrosion rates. This matter should be taken up by town planners and engineers when deciding on the location of new cities. A steel structure 1km from the coast and 3km from the coast will have a very big difference in the lifetime of its steel work. Though the chloride deposition rate has a lower impact on corrosion than SO<sub>2</sub> it is advisable to build away from the coast as much as possible because chloride deposition rates rise exponentially when coming near to the sea coast (Figure 15).

The study does an analysis on the energy related with galvanizing. This method of analyzing processes through energy will justify whether the process is economical in the aspect of energy. This kind of analysis was done because galvanizing will sacrifice one material which is zinc to prevent the corrosion of another, which is steel. The study simply reveals that the rate of corrosion of zinc is around 25 time slower than that of steel (at the atmosphere taken for the case study) hence the energy released by the corrosion of the total un protected steel mass will be around eight times the energy released by the mass of zinc sacrificed to protect the steel. This is reflected by the EROI being 7.7.

The energy analysis can be used to calculate the saving on carbon dioxide emissions by protecting steel using galvanizing. Knowing the corrosion rates of the island, a galvanizing plant can calculate the tonnage of steel salvaged through galvanizing and the tonnage of zinc sacrificed. If the total amount of CO<sub>2</sub> emission for producing a tone of steel and Zinc is known, the tonnage of CO<sub>2</sub> emission reduced can be calculated. The analysis has to be done in a detailed manner by owners of galvanizing plants or even construction companies using galvanized steel for its structures.

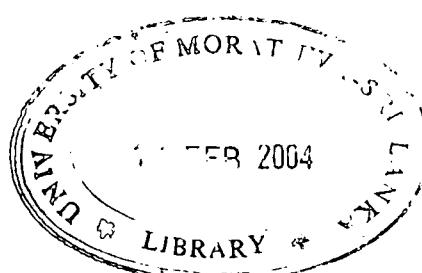

## 5.2 Limitations and Assumptions

The atmospheric factors such as rain fall, chloride and SO<sub>2</sub> concentration levels and humidity has been collected to predict the corrosion rates. One limitation is that the atmospheric factors will not reflect the local effects. One other limitation is that the SO<sub>2</sub> concentration in the atmosphere was not present for the whole country and the concentration of SO<sub>2</sub> has been predicted proportionate to the population density of the area. This prediction overlooks SO<sub>2</sub> emitting utilities in the area such as a large power plant. When predicting corrosion for a large area not taking in to account local effects could give inaccurate results. In situations when precise results for the corrosion rate is needed a more detailed study should be carried out. Being able to assign a corrosivity category as per ISO 9224 has given the opportunity to predict corrosion of copper, aluminum and steel in addition to zinc.

The assigning of corrosion categories could be done only with an assumption. In Table 11 the corrosivity category is given for the first year. In Table 12 the corrosivity category is given for the first ten years separately and over ten years separately. For zinc, the corrosion rates for each category whether it is the initial year, the initial 10 years or the time over 10 years are quite similar which can be referred in Table 11 and Table 12. Hence it is assumed that irrespective of the corrosion rate of zinc, is in the first year, first 10 years or over 10 years, each corrosivity category has the same corrosion rates. This assumption has given the liberty to assign a corrosivity category for an area just by looking at the corrosion rate of zinc without considering the age of the exposure. Due to this reason it is very straight forward to predict the service life of a zinc coating which is, just by dividing the coating thickness by the corrosion rate.

The energy conservation is calculated taking the figure of embedded energy of steel being 34 MJ/kg, but this figure varies when taking differently processed steel. For instance recycled steel has about one third the value of steel processed from the cradle. This applies to zinc as well. Hence in this case we talk only about material with embedded energy values given in the study.

Finally with all assumptions and limitations, this study shows how a simple phenomenon like corrosion could affect the society by wastage of energy and even link to global warming through contributing to CO<sub>2</sub> emissions in indirect ways.
